17

18 **Short title:** Fungicide resistance threatens health and crops

19

20 **One sentence summary:** Emerging resistance to antifungal drugs and fungicides is  
21 compromising our ability to treat fungal diseases in humans and in crops, necessitating new  
22 approaches to control endemic and emerging infections.

23

24

## 25 **Abstract**

26 We are witnessing an unprecedented rise in the rate of emergence of pathogenic fungi that  
27 are resistant to the limited number of commonly used antifungal agents. For example, the  
28 azoles are used for human and animal healthcare, for plant crop protection and in  
29 antifouling coatings and timber preservation. The ubiquity and dual-use of azoles has  
30 hastened the independent evolution of resistance in many environments. One consequence  
31 is an increasing risk emerging from naturally occurring 'opportunistic' and antifungal  
32 resistant pathogens, which challenge human healthcare. To avoid a global collapse in our  
33 ability to control fungal infections and to avoid critical failures in healthcare and food  
34 security, we must improve our stewardship of extant chemicals, promote novel antifungal  
35 discovery and leverage emerging technologies for alternative solutions.

36

## 37 **Introduction**

38 The rapid emergence of multidrug resistant pathogenic fungi and the better-publicised  
39 threat of antibiotic resistant bacteria both pose a considerable threat to disease control  
40 across diverse anthropogenic systems. These microbes respond adroitly to human-induced  
41 natural selection through chemical treatments, and nimbly hijack human globalisation  
42 pathways (1), so disseminating the problems world-wide. Today, crop-destroying fungi  
43 account for perennial yield losses of around 20% worldwide, with a further 10% loss post-  
44 harvest. Fungal impacts on human health are currently spiralling and global mortality  
45 caused by fungal diseases now exceeds that for malaria, or breast cancer, and is comparable  
46 to tuberculosis and HIV (2). These infections have, hitherto, been greatly neglected relative  
47 to other classes of infectious disease, despite occurring in more than a quarter of the  
48 world's population.

49 The first antifungal chemicals used in human healthcare, Nystatin and the polyenes, were  
50 discovered in the 1950s, whilst copper and sulphur fungicides were first used to control crop  
51 disease over 150 years ago. Today, systemic fungicides and antifungals are frontline  
52 treatments for fungal diseases in both humans and plants. This control can, however, be  
53 ephemeral as a result of the rapid development of resistance against the chemicals. Fungi  
54 have highly plastic genomes and reproduce rapidly producing large populations. The

55 combination of these properties quickly generates variants, selected for resistance. In plant  
56 pathogens, the pace of breakdown is enhanced by monoculture cropping practices, as large  
57 swathes of genetically uniform crops provide ideal feeding and breeding grounds for the  
58 rapid emergence of fungicide-resistant variants. In humans, long periods of prophylactic  
59 treatment in at-risk patients can similarly lead to the emergence of antifungal resistance (3).  
60 Resistance to all licensed systemic antifungals has been documented in clinical pathogens,  
61 although the rate of emergence varies between drug classes (Fig. 1) (3). Likewise, despite  
62 the wider range of fungicides licenced for use in agriculture, resistance to each main class of  
63 fungicides has emerged in some major pathogens (Fig. 1). This threat is exacerbated by the  
64 additional threat of withdrawal of some chemical classes due to regulatory changes in, for  
65 example the EU.

66 figure\_1.ai

## 67 **Antifungals for the treatment of fungal diseases in the clinic and the field**

68 The chemical control of fungal pathogens that cause diseases in animals and crops has  
69 progressed from the use of inorganic chemistries, through organic surface protectant  
70 chemistries, to systemic-acting fungicides. There are approximately nine-fold more  
71 antifungal compounds available to control crop diseases than to treat systemic animal  
72 infections. Licenced treatments in humans are limited to four frontline classes of drugs (Fig.  
73 1). The polyenes (such as amphotericin B) disrupt the structure of cell membranes by  
74 sequestering the fungal membrane sterol ergosterol. The pyrimidine analogue 5-  
75 fluorocytosine (5-FC) blocks pyrimidine metabolism and DNA synthesis. The newest class of  
76 antifungals, the echinocandins, inhibit (1-3)- $\beta$ -D glucan synthase and disrupt cell wall  
77 biosynthesis. The fourth and most widely used class of fungicides - the azoles, block  
78 ergosterol biosynthesis through inhibition of lanosterol 14- $\alpha$ -demethylase. Most fungicides  
79 for crop disease target mitochondrial function, the cytoskeleton, or ergosterol biosynthetic  
80 pathways (Fig. 1), although some specialist chemistries, such as the aza-naphthalenes for  
81 powdery mildew control, target other pathways.

82 It is important to highlight that the azoles are the dominant chemistry in the treatment of  
83 fungal infections in crops, humans and livestock, with 5 licenced clinical azole antifungals  
84 and 31 for crop protection.

## 85 **Parallel drivers of fungicide resistance in the clinic and the field**

86 Human population growth, urbanisation and economic prosperity have fuelled demands for  
87 increasing quantity and variety of food. Intensive agriculture has too often responded to this  
88 demand with crops bred for maximum productivity under the protection of broad-scale  
89 pesticide applications, inadvertently breeding out the plants' own defences. In parallel, the  
90 number of humans at risk from fungal infections is rising rapidly, as susceptible populations  
91 increase, either through age, medical interventions or HIV infection. Medical advances  
92 leading to greater initial survival of cancer or organ transplants can unfortunately leave  
93 patients susceptible to secondary attack from opportunistic fungi, leading to increasing use  
94 of antifungal drugs in clinical practice. Consequently, we are now witnessing an  
95 unprecedented worldwide increase in antifungal resistance, through both space and time  
96 (Fig. 2; Supp Table1).

97 Figure 2 lin.ai

98 The main drivers that underpin these changes are explored in Fig. 3. The global movement  
99 of people and trade in produce has hastened the free-flow of fungal pathogens from  
100 country to country, bringing new pathogens into contact with naïve hosts (1). In the clinical  
101 setting, new species of multidrug resistant pathogenic fungi are emerging. *Candida auris*,  
102 first described in Japan in 2009 following isolation from a patient's ear, is responsible for a  
103 rapidly increasing number of hospital-acquired invasive infections around the world (4). This  
104 fungus is now resistant to all clinical antifungals (5) and presents a particular threat to  
105 intensive-care units since it can survive normal decontamination protocols (6). The  
106 emergence of resistance in *Candida glabrata* has coincided with this species becoming the  
107 predominant bloodstream pathogen recovered from patients, due largely to the increasing  
108 prophylactic use of echinocandins and azoles (7). There is also a growing threat from  
109 filamentous pathogenic fungi which are intrinsically-resistant to a broad range of  
110 antifungals; for example *Aspergillus terreus* (8), *Scedosporium spp.* (9), *Fusarium spp* (10)  
111 and members of the mucorales (11). Simultaneously, we are witnessing the relentless

112 emergence of new races of plant-infecting fungi able to overcome both host defences and  
113 chemical treatments (12), as well as the evolution of these traits in existing major pathogens  
114 (13)(14). The first case of resistance against the MBCs was reported in 1969 (15) and now  
115 MBC resistance is known in over 90 plant pathogens (16). Azole resistance in a plant  
116 pathogen was first reported in 1981 (17), but azole resistance is generally partial, in contrast  
117 to the complete control failures seen for MBCs (18). QoI resistance was reported in field  
118 trials even before commercial introduction, and in wider field populations within two years  
119 of release (19). A new generation of SDHI fungicides has been introduced from 2007, but by  
120 2017, resistant field isolates had been found in 17 pathogen species (20). Pathogens with  
121 resistance against MBCs, azole, QoIs and SDHIs include the major wheat pathogen  
122 *Zymoseptoria tritici*, banana black sigatoka pathogen *Mycosphaerella fijiensis*, cereal  
123 powdery mildews *Blumeria graminis*, the emerging barley pathogen *Ramularia collo-cygni*  
124 and the apple scab fungus *Venturia inaequalis*. In *Botrytis cinerea* (a generalist pathogen  
125 that causes grey mould, particularly on soft fruits), resistance has been reported against 15  
126 different classes of systemic and protectant fungicides (21).

figure3.ai

127

## 128 **Parallel evolution of resistance mechanisms in the clinic and the field**

129 The strong and highly specific selective pressure exerted on fungi by single-site-inhibiting  
130 fungicides has resulted in similar adaptations arising over time in disparate fungal species.  
131 Indeed, this parallel evolution extends across clinical and plant pathogenic fungi, with the  
132 same key resistance mechanisms occurring independently in both.

133 Mutations resulting in conformation changes to the drug target site constitute the most  
134 common resistance mechanism in pathogenic fungi. They have been reported in candidin-  
135 resistant clinical pathogens; MBC, QoI and SDHI-resistant plant pathogens; and azole-  
136 resistant strains in field and clinic. A single mutation, G143A in cytochrome *b*, has emerged  
137 in the field in over 20 species under selection by QoIs (14). Moreover, the Y137F  
138 substitution in CYP51 has been found in multiple plant pathogens with partial azole  
139 resistance, and Y132F occurs at the equivalent residue in *C. albicans* (22). Promoter changes  
140 resulting in upregulation of the fungicide target are also common across clinical and plant  
141 pathogenic fungi (23). In *A. fumigatus*, tandem repeats in the *CYP51A* promoter region

142 occur together with downstream SNPs in the coding region, conferring a multi-azole  
143 resistance phenotype (24).

144 A third resistance mechanism involves reducing intracellular drug accumulation, through  
145 upregulation of efflux pumps. The upregulated efflux pumps may be ABC transporters or  
146 major facilitators, and their upregulation may result from promoter insertions or  
147 transcription factor gain-of-function mutations (3, 25).

148 Further resistance mechanisms have so far been identified only in clinical pathogens.  
149 Activation of stress response pathways by Hsp90 can unleash cryptic diversity, potentiating  
150 the evolution of resistance to azoles, echinocandins and polyenes in *Candida* and *Aspergillus*  
151 species (26). Structural genomic plasticity can result in resistance, with chromosome arm  
152 duplications leading to efflux pump and target-site overexpression in *C. albicans* (25, 27).  
153 Hypermutator strains of *C. glabrata* and *Cryptococcus* were recently reported, with the  
154 potential to evolve rapidly in response to host and drug selection (28, 29).

155

## 156 **Dual-use of azoles in the clinic and the field**

157 The azoles are the most widely-deployed class of fungicides in crop protection, totalling, for  
158 example, over 26% of all fungicides across the European Union (30). Azoles are also frontline  
159 drugs that protect humans and animals against pathogenic fungi. However, dual-use may  
160 have promoted azole resistance in an opportunistic pathogen of humans, threatening our  
161 ability to use this important class of drugs (30, 31). The saprotroph *Aspergillus fumigatus*  
162 colonises decaying vegetation in fields, forests and compost heaps and also infects  
163 immunocompromised humans. Multi-azole-resistant *A. fumigatus* has been recovered from  
164 both environmental and clinical samples across multiple continents. In the Netherlands,  
165 over 25% of *Aspergillus* infections carry azole-resistance alleles. Azoles are increasingly  
166 failing as frontline therapies, with associated patient mortality approaching 100% (32).  
167 Population genomic analyses have shown that azole-resistant alleles in *A. fumigatus* are  
168 associated with selective sweeps in regions of high azole-usage such as India (33).  
169 Moreover, recombination also occurs, generating new combinations of azole-resistance  
170 alleles (33). Investigations are now underway to assess the relative contributions of clinical  
171 and environmental selection to azole-resistant *A. fumigatus*, and to identify the most

172 problematic environmental applications of azoles. The potential conflict between the level  
173 of agricultural use and the durability of clinical effectiveness of azoles highlights how limited  
174 the antifungal toolbox is, where neither “side” can afford to lose a mode of action. Medicine  
175 and food security are both vital to human health (34), and both fields are in urgent need of  
176 a wider range of options to control fungal diseases.

177  
178 However, most cases of fungicide and antifungal resistance across field and clinic appear to  
179 have arisen by the repeated independent evolution of resistance to successive fungicides  
180 within numerous fungal species. This is where evolution of antifungal resistance differs  
181 fundamentally from antibacterial resistance, which is frequently transferred between  
182 animals and humans via the ‘mobilome’ of plasmids and phage (35). There is some evidence  
183 of horizontal gene transfer among fungi, (36) but this occurs on longer timescales than gene  
184 transfer among bacteria and the dynamics of resistance arising by this route is thus far  
185 negligible.

186

## 187 **Prospects for diversifying the toolbox for fungal control**

188 To counter the escalating risks of fungal disease we need to discover antifungal chemistries  
189 with novel modes of action, hinder the emergence of resistance in extant chemistries by  
190 better stewardship, and develop novel disease control strategies to avoid over-reliance on  
191 fungicides:

192 **Development of novel antifungals:** The rate of emergence of fungicide resistance (Fig. 2) is  
193 greater than the pace of fungicide discovery, and the long registration process for new  
194 compounds adds further delays. This parallels the situation for antibiotics. There is thus a  
195 need for increased research activity to develop new antifungal drugs (37). Recently, there  
196 has been significant progress in this field, with at least 11 antifungals in Phase I-II clinical  
197 trials and at least 2 in the AgChem pipeline. Several of these are derivatives of commonly  
198 used antifungal chemicals, such as ergosterol biosynthesis and cell wall biosynthesis  
199 inhibitors, engineered for higher efficacy, whilst others have new modes of action. Further,  
200 combining molecular modelling, combinatorial chemistry and high-throughput screening has  
201 the potential to develop chemistries with reduced resistance risk due to the complexity of  
202 the molecular changes required (38).

203 **Stewardship of existing compounds:** Robust global strategies are needed to slow the  
204 development of antifungal resistance. Combining different modes of action either in  
205 mixtures, or as alternating treatments, may slow the emergence of resistance. A clinical trial  
206 has shown that combinations of fluconazole, flucytosine and amphotericin-B can effectively  
207 treat HIV-associated cryptococcal meningitis (39). In agriculture, mixtures of fungicides with  
208 different modes of action are already widely recommended (40), with some formulations  
209 only available as mixed products. Where target-site mutations confer high levels of  
210 resistance lower doses of antifungals should be favoured (41, 42). However, this results in a  
211 trade-off between immediate effectiveness of treatment and slowing the selection of  
212 resistance. There is also a need to improve molecular diagnostics, both for the identification  
213 of fungal pathogens so antifungals can be used appropriately, and for the detection of  
214 specific resistance-alleles as the monitoring of resistance is a vital part of stewardship (43).

215

216 **Integrated disease management:** To reduce our reliance on chemical control alone we must  
217 develop more non-chemical control measures, to use where effective fungicides are no  
218 longer available, or to use in combination with fungicides to reduce the selective pressure  
219 on each component. In crops, the development of innate disease resistance through the  
220 selection of major pathogen-resistant (R) alleles is widely used to breed disease resistant  
221 cultivars. However, this approach is slow, with a 20 year lag from finding a suitable disease  
222 resistance gene to releasing it in commercial lines. Marker-assisted breeding can speed up  
223 the recombination of multiple disease resistance alleles, but still takes around a decade (44).  
224 Transgene cloning or gene editing is faster still (*circa* 2 years), but no crops with transgenic  
225 antifungal disease resistance have yet been released commercially. The high degree of  
226 specificity between host and pathogen in major R genes (45) means pathogens can also  
227 rapidly evolve to overcome this control measure. However, “evolution-smart” disease-  
228 resistant crops with pyramided pathogen resistance genes or mosaic deployment of  
229 resistant varieties may provide greater durability of disease control. Minor resistance genes  
230 (r), such as the antifungal chitinases and glucanases, carry the advantage of broad spectrum  
231 activity (46), but suffer the possible disadvantage of yield penalties as well as incomplete  
232 protection. Further sources of genetic disease resistance can be found in the gene pools of  
233 crop wild relatives, which may be introduced to modern crop varieties through introgression  
234 or transgenesis (44).

235

236 In humans, advances in combination anti-retroviral therapy to halt HIV-AIDS progression,  
237 gene therapies under development for cystic fibrosis, or tissue engineering for rejection-free  
238 transplants, can reduce vulnerability to fungal infections in such patient cohorts. Also, the  
239 first antifungal vaccine, against *C. albicans*, is undergoing clinical trials (47) and the use of  
240 bioengineered T cells to augment host immunity is being explored (48). Finally, the  
241 identification of human genetic biomarkers associated with susceptibility to fungal diseases,  
242 for example *PTX3* SNPs and *A. fumigatus* (49), provides a new path to identify patient groups  
243 in which antifungal treatments could be reduced.

244 The rapidly growing fields of synthetic biology and epigenomics are converging on antifungal  
245 treatments using RNA interference (RNAi). Bidirectional cross-kingdom microRNA (miRNA)  
246 trafficking between plants and fungi is being developed as a novel strategy to tackle  
247 pathogens (50), such as *Botrytis cinerea* which uses miRNA virulence effectors to silence  
248 host plant immune genes (51, 52). Current research avenues include identifying new targets  
249 for RNAi; and, crucially, developing systems for the stable and targeted delivery of RNA  
250 silencing, through genetic engineering of the host plant or exogenous application of  
251 synthetic RNA (51-53). Whilst such approaches have not yet been utilised to treat fungal  
252 infections in the clinic, the discovery and use of RNAi as a clinical antifungal approach  
253 represents a potentially transformational approach to tackling human fungal infections.

## 254 **Conclusion**

255 In both fungi and bacteria, the emergence of resistance has outpaced the supply of new  
256 antimicrobial compounds. There is an urgent need to increase the pipeline of new active  
257 compounds, to improve anti-resistance stewardship of existing products, and to diversify our  
258 control toolbox with the development of novel non-chemical control methods.

1193

## 1194 **Figure Legends**

1195

1196 **Figure 1.** Current antifungal drug classes used against plant and animal fungal infections,  
1197 and their known resistance mechanisms. There are six main classes of fungicides. These are  
1198 the morpholines, which inhibit two target sites within the ergosterol biosynthetic pathway,  
1199  $\Delta 14$ -reductase and  $\Delta 8$ - $\Delta 7$ -isomerase (this reduces the risk of target-site resistance, but their  
1200 intrinsic antifungal activity spectrum is narrower); the azoles used also in animal infections),  
1201 which target the ergosterol biosynthetic pathway; the MBCs (benzimidazoles), which  
1202 interfere with the cytoskeleton by binding to  $\beta$ -tubulin, so preventing the assembly of  
1203 microtubules; the Qols (strobilurins), and SDHIs (succinate dehydrogenase inhibitors), which  
1204 both inhibit the electron transfer chain of mitochondrial respiration, with the SDHIs  
1205 inhibiting complex II (succinate dehydrogenase) and the Qols inhibiting complex III  
1206 (cytochrome b, Quinone outside binding pocket) and the anilinopyrimidines which may  
1207 target mitochondrial signalling pathways.

1208

1209 **Figure 2.** Fungal species with reported antifungal resistance, by country. Increasing colour  
1210 intensity (red scale) reflects growing number of reports. Plant map reports spatio-temporal  
1211 records of resistance of crop pathogens to azoles. Human map reports spatio-temporal  
1212 records of resistance of the pathogens *Aspergillus fumigatus*; *Candida albicans*, *C. auris* and  
1213 *C. glabrata*; and *Cryptococcus gattii* and *C. neoformans* to azoles. Database derived from  
1214 peer-reviewed publications as of March 2018, reporting cases of resistance occurring up to  
1215 2017 available in Supplementary Information 1.

1216

1217 **Figure 3.** Evolutionary drivers of antifungal resistance: heritable variation, high reproductive  
1218 output and differential survival.

1219

1220

1221 **Supplementary content**

1222 **Supplementary Table 1.** Published reports of azole fungicide resistance in plant and clinical  
1223 pathogens, as illustrated in Figure 2. Plant records comprise spatio-temporal reports  
1224 (country and year) of resistance to azoles in any plant pathogen species. Human records  
1225 comprise spatio-temporal reports (country and year) of azole resistance in the pathogens  
1226 *Candida albicans*, *C. glabrata*, *C. auris*, *Cryptococcus* spp., and *Aspergillus fumigatus*.  
1227 Database derived from peer-reviewed publications as of March 2018, reporting cases of  
1228 resistance occurring up to 2017.

1229

1230 **Supplementary content**

1231

1232 Supplementary Table 1. Published reports of azole fungicide resistance in plant and clinical  
1233 pathogens, as illustrated in Figure 2. Plant records comprise spatio-temporal reports  
1234 (country and year) of resistance to azoles in any plant pathogen species. Human records  
1235 comprise spatio-temporal reports (country and year) of azole resistance in the pathogens  
1236 *Aspergillus fumigatus*; *Candida albicans*, *C. auris* and *C. glabrata*; and *Cryptococcus gattii*  
1237 and *C. neoformans*. Database derived from peer-reviewed publications as of March 2018,  
1238 reporting cases of resistance occurring up to 2017.
